(Dated: March 3, 2013)

Definitions of orbital angular momentum based on Wigner distributions are used as a framework to discuss the connection between the Ji definition of the quark orbital angular momentum and that of Jaffe and Manohar. We find that the difference between these two definitions can be interpreted as the change in the quark orbital angular momentum as it leaves the target in a DIS experiment. The mechanism responsible for that change is similar to the mechanism that causes transverse single-spin asymmetries in semi-inclusive deep-inelastic scattering.

## I. INTRODUCTION

Generalized parton distributions (GPDs) have been identified as a powerful tool to analyse the angular momentum decomposition of the nucleon [1]. Furthermore GPDs can also be used to create truly three-dimensional images of the nucleon in the form of impact parameter dependent parton distributions [2]. These images in a space where one dimension describes the light-cone momentum fraction and the other two dimensions describe the transverse position of the parton (relative to the transverse center of momentum) are complemented by Transverse Momentum dependent parton Distributions (TMDs) [3]. Wigner distributions provide a framework that allows a simultaneous description of GPDs and TMDs [4].

Orbital Angular Momentum (OAM) correlates the position and momentum of partons. One can thus utilize Wigner distributions, which simultaneously embody the distribution of position and momentum, to define OAM [5, 6]. However, in the definition of these distributions, care must be applied to ensure manifest gauge invariance. In general, this can be accomplished by connecting any non-local correlation function with a Wilson-line gauge link. Specifying a Wilson-line gauge link requires selecting a path along which the vector potential is evaluated. The choice of path raises the immediate issue of how the quantities defined using Wigner distributions (TMDs, OAM, ...) depend on that choice. This issue had become clear in the context of Single-Spin Asymmetries (SSAs) [7]. Indeed, while a straight-line gauge link definition of TMDs yields a vanishing Sivers effect [8, 9], the correct gauge link relevant for TMDs in Semi-Inclusive Deep-Inelastic Scattering (SIDIS) involves a detour to light-cone infinity [10] in order to properly include final-state interactions. In light-cone gauge, this subtlety had first been overlooked since in that gauge the Sivers effect solely arises from the contribution from the gauge-link piece at light-cone infinity [10].

With Wigner distributions and OAM defined through them these issues arise all over again [6, 11]. The main goal of this note is to address that dependence of OAM defined through Wigner distributions on the choice of path for the gauge link and to interpret the resulting difference between common definitions of OAM.

## II. ANGULAR MOMENTUM DECOMPOSITIONS

Since the famous EMC experiments revealed that only a small fraction of the nucleon spin is due to quark spins [12], there has been a great interest in ‘solving the spin puzzle’, i.e. in decomposing the nucleon spin into contributions from quark/gluon spin and orbital degrees of freedom. In this effort, the Ji decomposition [1]

$$\frac{1}{2} = \frac{1}{2} \sum_q \Delta q + \sum_q L_q^z + J_g^z \quad (1)$$

appears to be very useful: through GPDs, not only the quark spin contributions  $\Delta q$  but also the quark total angular momenta  $J_q \equiv \frac{1}{2} \Delta q + L_q^z$  (and by subtracting the spin piece also the the quark orbital angular momenta  $L_q^z$ ) entering this decomposition can be accessed experimentally. The terms in (1) are defined as expectation values of the corresponding terms in the angular momentum tensor

$$M^{0xy} = \sum_q \frac{1}{2} q^\dagger \Sigma^z q + \sum_q q^\dagger \left( \vec{r} \times i \vec{D} \right)^z q + \left[ \vec{r} \times \left( \vec{E} \times \vec{B} \right) \right]^z \quad (2)$$

in a nucleon state with zero momentum. Here  $i \vec{D} = i \vec{\partial} - g \vec{A}$  is the gauge-covariant derivative. The main advantages of this decomposition are that each term can be expressed as the expectation value of a manifestly gauge invariant

local operator and that the quark total angular momentum  $J^q = \frac{1}{2}\Delta q + L^q$  can be related to GPDs [1] and is thus accessible in deeply virtual Compton scattering and deeply virtual meson production and can also be calculated in lattice gauge theory. Recent lattice calculations of GPDs [13] yielded the surprising result that the light quark orbital angular momentum (OAM) is consistent with  $L^u \approx -L^d$ , i.e.  $L^u + L^d \approx 0$ . Unless there is a large contribution from disconnected quark loops [14], that had been so far omitted, this would imply that  $J^g \approx \frac{1}{2} \cdot 0.7$  represents the largest piece in the nucleon spin decomposition.

Jaffe and Manohar have proposed an alternative decomposition of the nucleon spin, which does have a partonic interpretation [15], and in which also two terms,  $\frac{1}{2}\Delta q$  and  $\Delta G$ , are experimentally accessible

$$\frac{1}{2} = \frac{1}{2} \sum_q \Delta q + \sum_q \mathcal{L}^q + \Delta G + \mathcal{L}^g. \quad (3)$$

The individual terms in (3) can be defined as matrix elements of the corresponding terms in the +12 component of the angular momentum tensor

$$M^{+12} = \frac{1}{2} \sum_q q_+^\dagger \gamma_5 q_+ + \sum_q q_+^\dagger \left( \vec{r} \times i\vec{\partial} \right)^z q_+ + \varepsilon^{+-ij} \text{Tr} F^{+i} A^j + 2 \text{Tr} F^{+j} \left( \vec{r} \times i\vec{\partial} \right)^z A^j \quad (4)$$

for a nucleon polarized in the  $+\hat{z}$  direction. The first and third term in (3),(4) are the ‘intrinsic’ contributions (no factor of  $\vec{r} \times$ ) to the nucleon’s angular momentum  $J^z = +\frac{1}{2}$  and have a physical interpretation as quark and gluon spin respectively, while the second and fourth term can be identified with the quark/gluon OAM. Here  $q_+ \equiv \frac{1}{2} \gamma^- \gamma^+ q$  is the dynamical component of the quark field operators, and light-cone gauge  $A^+ \equiv A^0 + A^z = 0$  is implied. The residual gauge invariance can be fixed by imposing anti-periodic boundary conditions  $\vec{A}_\perp(\mathbf{x}_\perp, \infty) = -\vec{A}_\perp(\mathbf{x}_\perp, -\infty)$  on the transverse components of the vector potential.  $\mathcal{L}$  also naturally arises in a light-cone wave function description of hadron states, where  $\frac{1}{2} = \frac{1}{2} \sum_q \Delta q + \Delta G + \mathcal{L}$ , in the sense of an eigenvalue equation, is manifestly satisfied for each Fock component individually [16].

A variation of (1) has been suggested in Ref. [17], where part of  $L_q^z$  is attributed to the glue as ‘potential angular momentum’. Other decompositions, in which only one term is experimentally accessible, will not be discussed in this brief note.

### III. ORBITAL ANGULAR MOMENTUM FROM WIGNER DISTRIBUTIONS

Wigner distributions can be defined as defined as off forward matrix elements of non-local correlation functions [4, 6, 18]

$$W^{\mathcal{U}}(k^+ = xP^+, \vec{b}_\perp, \vec{k}_\perp) \equiv \int \frac{d^2 \vec{q}_\perp}{(2\pi)^2} \int \frac{d^2 \xi_\perp d\xi^-}{(2\pi)^3} e^{-i\vec{q}_\perp \cdot \vec{b}_\perp} e^{i(xP^+ \xi^- - \vec{k}_\perp \cdot \vec{\xi}_\perp)} \langle P' S' | \bar{q}(0) \Gamma \mathcal{U}_{0\xi} q(\xi) | PS \rangle \quad (5)$$

with  $P^+ = P'^+$ ,  $P_\perp = -P'_\perp = \frac{q_\perp}{2}$ . Throughout this paper, we will chose  $\vec{S} = \vec{S}' = \hat{z}$ . Furthermore, we will focus on the ‘good’ component by selecting  $\Gamma = \gamma^+$ . In order to ensure manifest gauge invariance, a Wilson line gauge link  $\mathcal{U}_{0\xi}$  connecting the quark field operators at position 0 and  $\xi$  must be included. The issue of choice of path for the Wilson line will be addressed below.

In terms of Wigner distributions, quark OAM can be defined as [5]

$$L_{\mathcal{U}} = \int dx d^2 \vec{b}_\perp d^2 \vec{k}_\perp \left( \vec{b}_\perp \times \vec{k}_\perp \right)_z W^{\mathcal{U}}(x, \vec{b}_\perp, \vec{k}_\perp). \quad (6)$$

No issues with the Heisenberg uncertainty principle arise here since only perpendicular combinations of position  $\vec{b}_\perp$  and momentum  $\vec{k}_\perp$  are needed simultaneously in order to evaluate the integral.

A straight line connecting 0 and  $\xi$  for the Wilson line in  $\mathcal{U}_{0\xi}$  is often the most natural choice, resulting in [6]

$$L_{straight}^q \equiv \int dx d^2 \vec{b}_\perp d^2 \vec{k}_\perp \left( \vec{b}_\perp \times \vec{k}_\perp \right)_z W^{straight}(x, \vec{b}_\perp, \vec{k}_\perp) = L_{Ji}^q \equiv \frac{\int d^3 \vec{r} \langle PS | q^\dagger(\vec{r}) \left( \vec{r} \times i\vec{D} \right) q(\vec{r}) | PS \rangle}{\langle PS | PS \rangle} \quad (7)$$

for a nucleon polarized in the  $+\hat{z}$  direction, where  $i\vec{D} = i\vec{\partial} - g\vec{A}(\vec{r})$  is the usual gauge-covariant derivative. This is also the angular momentum that appears in the Ji-decomposition of the angular momentum for a nucleon (1).

FIG. 1: Illustration of the path for the Wilson line gauge link used to define the Wigner distribution  $W^{+LC}$  (5).

However, depending on the context, other choices for the path in the Wilson link  $\mathcal{U}$  should be made. Indeed, in the context of TMDs probed in SIDIS the path should be taken to be a straight line to  $x^- = \infty$  along (or very close to) the light-cone. This particular choice ensures proper inclusion of the Final State Interactions (FSI) experienced by the struck quark as it leaves the nucleon along a nearly light-like trajectory in the Bjorken limit. However, a Wilson line to  $\xi^- = \infty$ , for fixed  $\xi_\perp$  is not yet sufficient to render Wigner distributions manifestly gauge invariant, but a link at  $x^- = \infty$  must be included to ensure manifest gauge invariance. While the latter may be unimportant in some gauges, it is crucial in light-cone gauge for the description of TMDs relevant for SIDIS [10].

Let  $\mathcal{U}_{0\xi}^{+LC}$  be the Wilson path ordered exponential obtained by first taking a Wilson line from  $(0^-, \vec{0}_\perp)$  to  $(\infty, \vec{0}_\perp)$ , then to  $(\infty, \vec{\xi}_\perp)$ , and then to  $(\xi^-, \vec{\xi}_\perp)$ , with each segment being a straight line (Fig. 1) [11]. The shape of the segment at  $\infty$  is irrelevant as the gauge field is pure gauge there, but it is still necessary to include a connection at  $\infty$  and for simplicity we pick a straight line. Likewise, with a similar 'staple' to  $-\infty$  we define the Wilson path ordered exponential  $\mathcal{U}_{0\xi}^{-LC}$ , and using those light-like gauge links we define

$$W^{\pm LC}(k^+ = xP^+, \vec{b}_\perp, \vec{k}_\perp) \equiv \int \frac{d^2 \vec{q}_\perp}{(2\pi)^2} \int \frac{d^2 \xi_\perp d\xi^-}{(2\pi)^3} e^{i(xP^+ \xi^- - \vec{k}_\perp \cdot \vec{\xi}_\perp)} \langle P' S' | \bar{q}(0) \Gamma \mathcal{U}_{0\xi}^{\pm LC} q(\xi) | PS \rangle. \quad (8)$$

This definition for  $W^{+LC}$  the same as that in [11] and similar to that of  $W_{LC}$  in Ref. [6], except that the link segment at  $x^- = \infty$  was not included in the definition of  $W_{LC}$  [6]. If boundary conditions are chosen such that  $\vec{A}_\perp(+\infty, \vec{r}_\perp) = 0$ , but  $\vec{A}_\perp(-\infty, \vec{r}_\perp) \neq 0$  then  $W_{LC}$  from Ref. [6] becomes equal to  $W^{+LC}$ . However, as we will discuss below, the piece at  $x^- = \infty$  does not contribute to the OAM [11] even though it contributes to TMDs.

In light-cone gauge  $A^+ = 0$  the Wilson lines to  $x^- = \infty$  become trivial and only the piece at  $x^- = \infty$  remains. While the gauge field at light-cone infinity  $\vec{A}_\perp(\pm\infty, \vec{r}_\perp)$  cannot be neglected or set equal to zero in light-cone gauge, it can be chosen to satisfy anti-symmetric boundary conditions

$$\vec{\alpha}_\perp(\vec{r}_\perp) \equiv \vec{A}_\perp(\pm\infty, \vec{r}_\perp) = -\vec{A}_\perp(\pm\infty, \vec{r}_\perp). \quad (9)$$

This choice maintains manifest PT (sometimes called 'light-cone parity') invariance.

Using these Wigner distributions, one can now proceed to introduce orbital angular momentum as

$$\begin{aligned} \mathcal{L}_\pm^q &\equiv \int dx d^2 \vec{b}_\perp d^2 \vec{k}_\perp \left( \vec{b}_\perp \times \vec{k}_\perp \right)^z W^{\pm LC}(x, \vec{b}_\perp, \vec{k}_\perp) \\ &= \frac{\int d^3 \vec{r} \langle PS | \bar{q}(\vec{r}) \gamma^+ \left[ \vec{r} \times \left( i\vec{\partial} \pm g\vec{\alpha}_\perp(\vec{r}_\perp) \right) \right]^z q(\vec{r}) | PS \rangle}{\langle PS | PS \rangle}, \end{aligned} \quad (10)$$

and similar for the glue. Eq. (10) differs from

$$\mathcal{L}^q = \frac{\int d^3 \vec{r} \langle PS | \bar{q}(\vec{r}) \gamma^+ \left( \vec{r} \times i\vec{\partial} \right)^z q(\vec{r}) | PS \rangle}{\langle PS | PS \rangle} \quad (11)$$

(denoted  $\tilde{\mathcal{L}}^q$  in Ref. [6]) by the contribution from the gauge field  $\pm \vec{\alpha}_\perp$  at  $\pm\infty$ .  $\mathcal{L}^q$  is also identical to the quark OAM appearing in the Jaffe-Manohar decomposition of the nucleon spin (3).

#### IV. CONNECTIONS BETWEEN DIFFERENT DEFINITIONS FOR OAM

First of all from PT invariance one finds that  $\mathcal{L}_+^q = \mathcal{L}_-^q$  [11]. As a corollary, since the piece at  $\pm\infty$  cancels in the average both must thus be identical to the OAM appearing in the Jaffe-Manohar decomposition

$$\mathcal{L}^q = \frac{1}{2} (\mathcal{L}_+^q + \mathcal{L}_-^q) = \mathcal{L}_+^q = \mathcal{L}_-^q. \quad (12)$$

Therefore, even though the gauge link at  $x^- = \pm\infty$  is essential for the description of TMDs [10], it does not contribute to the OAM. One might have anticipated this result already as  $\mathcal{L}^q$  is insensitive to the residual gauge invariance after selecting  $A^+ = 0$  [19].

To establish the connection with the orbital angular momentum entering the Ji-decomposition, we consider (for simplicity in light-cone gauge)

$$\mathcal{L}^q - L^q = \mathcal{L}_+^q - L^q = \frac{\int d^3\vec{r} \langle PS | \bar{q}(\vec{r}) \gamma^+ \left[ \vec{r}_\perp \times \left( g \vec{\alpha}_\perp(\vec{r}_\perp) - g \vec{A}_\perp(\vec{r}) \right) \right]_z q(\vec{r}) | PS \rangle}{\langle PS | PS \rangle}. \quad (13)$$

As discussed in Ref. [20], we replaced  $\gamma^0 \rightarrow \gamma^+$  for a nucleon at rest in the definition for  $L^q$ .

Using (in light-cone gauge  $A^+ = 0$  and hence  $G^{+i} = \partial_- A^i$ )

$$\alpha^i(\vec{r}_\perp) - A^i(\vec{r}) = \int_{r^-}^{\infty} dr^- \partial_- A_\perp^i(\vec{r}) = \int_{r^-}^{\infty} dx^- G^{+i}(\vec{r}) \quad (14)$$

and noting that

$$T^z(\vec{r}) \equiv g (x G^{+y}(\vec{r}) - y G^{+x}(\vec{r})) \quad (15)$$

represents the  $\hat{z}$  component of the torque that acts on a particle moving with (nearly) the velocity of light in the  $-\hat{z}$  direction – the direction in which the ejected quark moves. Thus the difference between the (forward) light-cone and the local definitions of the orbital angular momentum is the change in orbital angular momentum as the quark moves through the color field created by the spectators

$$\mathcal{L}^q - L^q = \frac{\int d^3\vec{r} \langle PS | \bar{q}(\vec{r}) \gamma^+ \int_{r^-}^{\infty} dy^- T^z(y^-, \vec{r}_\perp) q(\vec{r}) | PS \rangle}{\langle PS | PS \rangle}. \quad (16)$$

Therefore, while  $L^q$  represents the local and manifestly gauge invariant OAM of the quark *before* it has been struck by the  $\gamma^*$ ,  $\mathcal{L}^q$  represents the gauge invariant OAM *after* it has left the nucleon and moved to  $\infty$ . This physical interpretation of the difference between the TMD based (i.e. Jaffe-Manohar) definition of quark OAM with a light-cone staple and the local definition represents the main result of this paper.

It is instructive to compare this result with a similar result in the context of the Sivers effect [8], where  $\alpha^i(\mathbf{r}_\perp)$  also plays a crucial role. Indeed, the average transverse momentum of quarks of flavor  $q$  after being ejected from the target in DIS can be represented as [22]

$$\langle k_q^i \rangle = \frac{\int d^3\vec{r} \langle PS | \bar{q}(\vec{r}) \gamma^+ g \int_{r^-}^{\infty} dy^- G^{+i}(y^-, \vec{r}_\perp) q(\vec{r}) | PS \rangle}{\langle PS | PS \rangle}, \quad (17)$$

which has an intuitive interpretation of integrating the transverse force along the quark's trajectory to yield the net impulse acquired from the final state interactions. In contradistinction to OAM, in the case of transverse momentum the initial average value is zero. Nevertheless, using (14) we can rewrite (17) as [23]

$$\langle k_q^i \rangle = \frac{\int d^3\vec{r} \langle PS | \bar{q}(\vec{r}) \gamma^+ g [\alpha_\perp^i(\vec{r}_\perp) - g A_\perp^i(\vec{r})] q(\vec{r}) | PS \rangle}{\langle PS | PS \rangle} \int dx d^2\vec{b}_\perp d^2\vec{k}_\perp k_\perp^i \left[ W^{+LC}(x, \vec{b}_\perp, \vec{k}_\perp) - W^{straight}(x, \vec{b}_\perp, \vec{k}_\perp) \right]. \quad (18)$$

It is easy to see that a torque as appearing in (16) may exist by considering a quark moving through a (color-) magnetic dipole field caused by the spectators. Because of the overall color-neutrality, this is similar to a positively charged particle moving through the magnetic field caused by negative spectators in QED. For spectator spins/OAMs that are oriented in the  $+\hat{z}$  axis one would thus expect a dipole field as shown in Fig. 2. All quarks ejected in the  $-\hat{z}$  direction pass through the region of outward pointing radial magnetic field component, but only those originating in the bottom portion also move through regions of inward pointing radial component, i.e. for quarks ejected in the  $-\hat{z}$

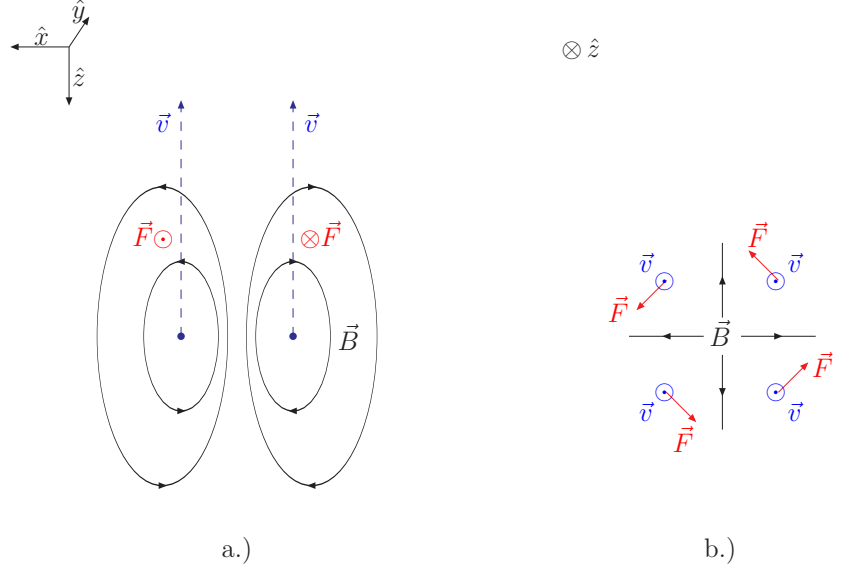

FIG. 2: Illustration of the torque acting on the struck quark in the  $-\hat{z}$  direction through a color-magnetic dipole field caused by the spectators. a.) side view; b.) top view. In this example the  $\hat{z}$  component of the torque is negative as the quark leaves the nucleon.

direction the regions of outward pointing radial component dominate. One would thus expect more torque in the  $-\hat{z}$  direction than in  $+\hat{z}$  direction. This example not only illustrates that the net change in OAM as the quark leaves the nucleon is nonzero, but also suggests what the sign of  $\mathcal{L}^q - L^q$  might be: for  $d$  quarks the spins of the spectators are positively correlated with the nucleon spin, corresponding to a situation similar to the one depicted in Fig. 2, and  $\mathcal{L}^q - L^q$  should thus be negative. For  $u$  quarks the situation is less obvious since there should be a partial cancellation between the  $d$  quark spectator and the  $u$  quark spectator. For an positron (electron) moving through its own dipole field in QED the magnetic dipole field is reversed. This illustrates why  $\mathcal{L}^e - L^e$  is positive [20].

The above example of a magnetic dipole field (Fig. 2) also illustrates why the vector potential at the boundary does not contribute to the OAM:

$$\alpha^i(\vec{r}_\perp) = \frac{1}{2} [A^i(\infty, \vec{r}_\perp) - A^i(-\infty, \vec{r}_\perp)] = \frac{1}{2} \int_{-\infty}^{\infty} dr^- G^{+i}(r^-, \vec{r}_\perp) = 0, \quad (19)$$

as we can replace  $dr^- \rightarrow -dz$  for a static field and there is a cancellation between positive  $z$  (magnetic field pointing inward) and negative  $z$  (magnetic field pointing outward).

## V. SUMMARY

The angular momenta appearing in the Jaffe-Manohar formalism are identical to Wigner function based definitions of OAM utilizing light-cone staples. We have used this result to understand the difference between the Jaffe-Manohar definition of OAM and Ji's local manifestly gauge invariant definition of OAM can be related to the torque that acts on a quark in longitudinally polarized DIS. In other words, while one definition (Ji) yields the net OAM quarks *before* absorbing the virtual photon, the (light-cone staple) Wigner distribution based definition (JM) yields the net OAM after the quark has escaped to infinity. We thus now understand the physics through which these two definitions are related to one another.

This is very similar to the situation in the context of TMDs where the difference between the average quark transverse momentum after it has left the target (from Sivers function) and before it has left the target (where it is zero), can be related to the difference of TMDs defined with a light-cone staple shaped Wilson line gauge link versus one defined with a straight-line gauge link.

Unfortunately, no experiment has been identified to measure the OAM of quarks after they have been ejected in DIS. Nevertheless, we believe that the above interpretation will help to develop a more complete picture of the nucleon spin.
